The Leslie Population Model in a Random Environment: Consider the Leslie model of a population with three classes (call them J for juveniles, Y for young adults, and A for adults) used in Project #4. Suppose the population starts at time zero with 40% in the J class, 35% in the Y class and 25% in the A class and there are a total of 100 individuals present then. Suppose that the population projection matrix is:

\[
P = \begin{bmatrix}
0 & 1 & F \\
.5 & 0 & 0 \\
0 & q & 1
\end{bmatrix}
\]

where the parameter q is calculated by

\[
q = \frac{((\text{your age in years})/50 + (\text{the number of your birthmonth})/12)}{2}.
\]

Thus if you were born in July of 1980, so you are 26 years old,

\[
q = \frac{26/50 + 7/12}{2} = 0.552
\]

(use three significant digits, please). Now suppose the adult fecundity F varies from year to year according to a uniform distribution, with an average value of 5 and with a deviation about that, so that the fecundity varies over the interval \((F\text{-deviation}, F\text{+deviation})\).

Making use of the Matlab code in the file ranleslie.m, do the following:

Calculate your value of p and for values of deviation of 1, 2, 3, and 4:

(a) Determine the population size at the end of a time period of length 101, repeat the experiment 200 times and compute the mean and standard deviation of population size at time 101, and show a histogram of it’s values.

(b) Determine the geometric mean growth rate of the population’s total size by computing this over the single time-step growth rates from time 20 to time 100, repeat the experiment 200 times and compute the mean and standard deviation of the geometric mean growth rate, and show a histogram of it’s values.

(c) Summarize your results in a chart for the cases of deviation = 1, 2, 3, 4, showing the means and standard deviations computed in (a) and (b). Discuss these results and in particular describe how a larger random variation in fecundities affects the population size and the geometric growth rate.
